

Evolutionary Dataset Optimisation: learning algorithm quality through evolution

Henry Wilde, Vincent Knight, Jonathan Gillard

Abstract In this paper we propose a new method for learning how algorithms perform. Classically, algorithms are compared on a finite number of existing (or newly simulated) benchmark data sets based on some fixed metric. The algorithm(s) with the smallest value of this metric are chosen to be the ‘best performing’.

We offer a new approach to flip this paradigm. We instead aim to gain a richer picture of the performance of an algorithm by generating artificial data through genetic evolution, the purpose of which is to create populations of datasets for which a particular algorithm performs well. These data sets can be studied to learn as to what attributes lead to a particular progress of a given algorithm.

Following a detailed description of the algorithm as well as a brief description of an open source implementation, a number of numeric experiments are presented to show the performance of the method.

1 Introduction

This work presents a novel approach to learning the quality and performance of an algorithm through the use of evolution. When an algorithm is developed to solve a given problem, the designer is presented with questions about the performance of their proposed method, and its relative performance against existing methods. This is an inherently difficult task. However, under the current paradigm, the standard response to this situation is to use a known fixed set of datasets and a common metric amongst the proposed method and its competitors. The algorithm is then assessed based on this metric with minimal consideration for both the appropriateness or reliability of the datasets being used, and the robustness of the method in question.

This notion is not so easily observed when travelling in the opposite direction. Suppose that, instead, the benchmark was a dataset of particular interest and a preferable algorithm was to be determined for some task. There exist a number of methods employed across disciplines to complete this task that take into account the characteristics of the data and the context of the research problem. These methods include the use of diagnostic tests. For instance, in the case of clustering, if the data displayed an indeterminate number of non-convex blobs, then one could recommend that an appropriate clustering algorithm would be DBSCAN [5]. Otherwise, for scalability, k -means may be chosen.

The approach presented in this work aims to flip the paradigm described here by allowing the data itself to be unfixed. This fluidity in the data is achieved by generating data for which the algorithm performs well (or better than some other) through the use of an evolutionary algorithm. The purpose of doing so is not to simply create a bank of useful datasets but rather to allow for the subsequent studying of these datasets. In doing so, the attributes and characteristics which lead to the success (or failure) of the algorithm may be described, giving a broader understanding of the algorithm on the whole.

Fig. 1: On the right: the current path for selecting some algorithm(s) based on their validity and performance for a given dataset. On the left: the proposed flip to better understand the space in which ‘good’ datasets exist for an algorithm.

This proposed flip has a number of motivations, and below is a non-exhaustive list of some of the problems that are presented by the established evaluation paradigm:

1. How are these benchmark examples selected? There is no true measure of their reliability other than their frequent use. In some domains and disciplines there are well-established benchmarks so those found through literature may well be reliable, but in others less so.
2. Sometimes, when there is a lack of benchmark examples, a ‘new’ dataset is simulated to assess the algorithm. This begs the question as to how and why that simulation is created. Not only this, but the origins of existing benchmarks is often a matter of convenience rather than their merit.
3. In disciplines where there are established benchmarks, there may still be underlying problems around the true performance of an algorithm:
 - (i) As an example, work by Torralba and Efros [22] showed that image classifiers trained and evaluated on a particular dataset, or datasets, did not perform reliably when evaluated using other benchmark datasets that were determined to be similar. Thus leading to a model which lacks robustness.
 - (ii) The amount of learning one can gain as to the characteristics of data which lead to good (or bad) performance of an algorithm is constrained to the finite set of attributes present in the benchmark data chosen in the first place.

Evolutionary algorithms (EAs) have been applied successfully to solve a wide array of problems - particularly where the complexity of the problem or its domain are significant. These methods are highly

adaptive and their population-based construction (displayed in Figure 2) allows for the efficient solving of problems that are otherwise beyond the scope of traditional search and optimisation methods.

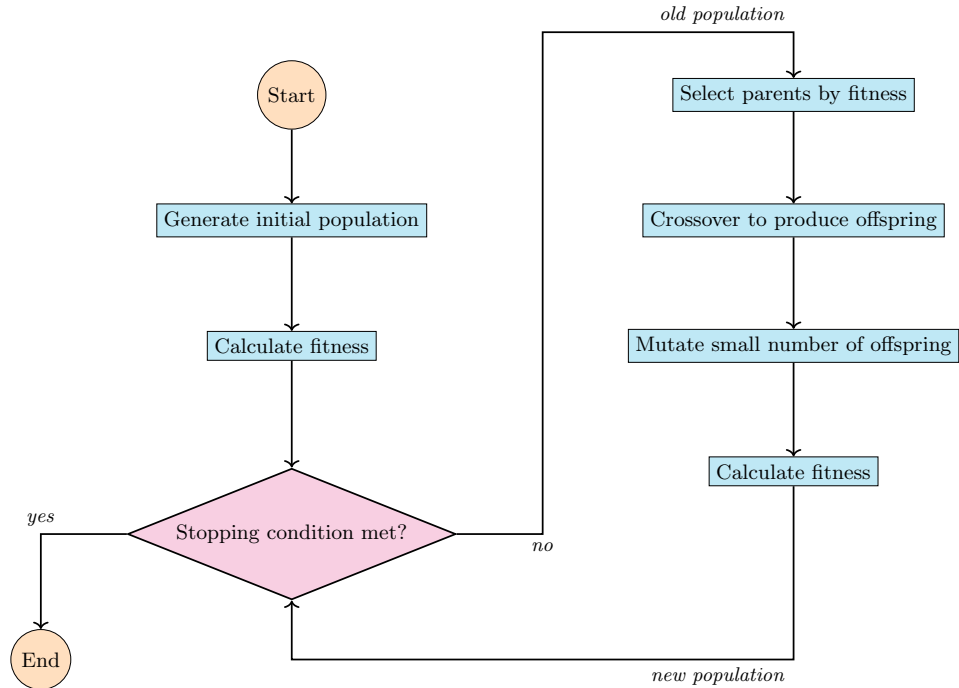

Fig. 2: A general schematic for an evolutionary algorithm.

The use of EAs to generate artificial data is not a new concept. Its applications in data generation have included developing methods for the automated testing of software [9, 15, 19] and the synthesis of existing or confidential data [3]. Such methods also have a long history in the parameter optimisation of algorithms, and recently in the automated design of convolutional neural network (CNN) architecture [20, 21].

Other methods for the generation or synthesis of artificial data include simulated annealing [13] and generative adversarial networks (GANs) [6]. The unconstrained learning style of methods such as CNNs and GANs aligns with that proposed in this work. By allowing the EA to explore and learn about the search space in an organic way, less-prejudiced insight can be established that is not necessarily reliant on any particular framework or agenda.

Note that the proposed methodology is not simply to use an EA to optimise an algorithm over a search space with fixed dimension or datatype such as those set out in [3]. The size and sample space itself is considered as a property that can be traversed through the algorithm.

2 The evolutionary algorithm

2.1 Structure

In this section, the details of an algorithm that generates data for which a given function or, equivalently, an algorithm which is well suited, is described. This algorithm is to be referred to as “Evolutionary Dataset Optimisation” (EDO).

The EDO method is built as an evolutionary algorithm which follows a traditional (generic) schema with some additional features that keep the objective of artificial data generation in mind. With that, there are a number of parameters that are passed to EDO; the typical parameters of an evolutionary algorithm are a fitness function, f , which maps from an individual to a real number, as well as a population size, N , a maximum number of iterations, M , a selection parameter, b , and a mutation probability, p_m . In addition to these, EDO takes the following parameters:

- Limits on the number of rows an individual dataset can have:

$$R \in \left\{ (r_{\min}, r_{\max}) \in \mathbb{N}^2 \mid r_{\min} \leq r_{\max} \right\}$$

- Limits on the number of columns a dataset can have:

$$C := (C_1, \dots, C_{|\mathcal{P}|}) \text{ where } C_j \in \left\{ (c_{\min}, c_{\max}) \in (\mathbb{N} \cup \{\infty\})^2 \mid c_{\min} \leq c_{\max} \right\}$$

for each $j = 1, \dots, |\mathcal{P}|$. That is, C defines the minimum and maximum number of columns a dataset may have from each distribution in \mathcal{P} .

- A set of probability distribution families, \mathcal{P} . Each family in this set has some parameter limits which form a part of the overall search space. For instance, the family of normal distributions, denoted by $N(\mu, \sigma^2)$, would have limits on values for the mean, μ , and the standard deviation, σ .
- A maximum number of “subtypes” for each family in \mathcal{P} . A subtype is an independent copy of the family that progresses separate from the others. These are the actual distribution objects which are traversed in the optimisation.
- A probability vector to sample distributions from \mathcal{P} , $w = (w_1, \dots, w_{|\mathcal{P}|})$.
- A second selection parameter, $l \in [0, 1]$, to allow for a small proportion of “lucky” individuals to be carried forward.
- A shrink factor, $s \in [0, 1]$, defining the relative size of a component of the search space to be retained after adjustment.

The concepts discussed in this section form the mechanisms of the evolutionary dataset optimisation algorithm. To use the algorithm practically, these components have been implemented in Python as a

library built on the scientific Python stack [14, 17]. The library is fully tested and documented (at <https://edo.readthedocs.io>) and is freely available online under the MIT license [4]. The EDO implementation was developed to be consistent with the best practices of open source software development.

Algorithm 1: The evolutionary dataset optimisation algorithm

Input: $f, N, R, C, \mathcal{P}, w, M, b, l, p_m, s$
Output: A full history of the populations and their fitnesses.
begin
 create initial population of individuals
 find fitness of each individual
 record population and its fitness
 while *current iteration less than the maximum* **and** *stopping condition not met* **do**
 select parents based on fitness and selection proportions
 use parents to create new population through crossover and mutation
 find fitness of each individual
 update population and fitness histories
 if *adjusting the mutation probability* **then**
 | update mutation probability
 end
 if *using a shrink factor* **then**
 | shrink the mutation space based on parents
 end
 end
end

Algorithm 2: Creating a new population

Input: parents, $N, R, C, \mathcal{P}, w, p_m$
Output: A new population of size N
begin
 add parents to the new population
 while *the size of the new population is less than N* **do**
 sample two parents at random
 create an offspring by crossing over the two parents
 mutate the offspring according to the mutation probability
 add the mutated offspring to the population
 end
end

The statement of the EDO algorithm is presented here to lay out its general structure from a high level perspective. Lower level discussion is provided below where additional algorithms for the individual creation, evolutionary operator and shrinkage processes are given along with diagrams (where appropriate).

Note that there are no defined processes for how to stop the algorithm or adjust the mutation probability, p_m . This is down to their relevance to a particular use case. Some examples include:

- Stopping when no improvement in the best fitness is found within some K consecutive iterations [11].

- Utilising global behaviours in fitness to indicate a stopping point [12].
- Regular decreasing in mutation probability across the available attributes [10].

2.2 Individuals

Evolutionary algorithms operate in an iterative process on populations of individuals that each represent a solution to the problem in question. In a genetic algorithm, an individual is a solution encoded as a bit string of, typically, fixed length and treated as a chromosome-like object to be manipulated. In EDO, as the objective is to generate datasets and explore the space in which datasets exist, there is no encoding. As such the distinction is made that EDO is an evolutionary algorithm.

As is seen in Figure 3, an individual’s creation is defined by the generation of its columns. A set of instructions on how to sample new values (in mutation, for instance, Section 2.5) for that column are recorded in the form of a probability distribution. These distributions are sampled and created from the families passed in \mathcal{P} . In EDO, the produced datasets and their metadata are manipulated directly so that the biological operators can be designed and be interpreted in a more meaningful way as will be seen later in this section.

However, one should not assume that the columns are a reliable representative of the distribution associated with them, or vice versa. This is particularly true of “shorter” datasets with a small number of rows, whereas confidence in the pair could be given more liberally for “longer” datasets with a larger number of rows. In any case, appropriate methods should be

Fig. 3: An example of how an individual is first created.

Algorithm 3: Creating an individual

Input: R, C, \mathcal{P}, w
Output: An individual defined by a dataset and some metadata
begin
 sample a number of rows and columns
 create an empty dataset
 for *each column in the dataset* **do**
 sample a distribution from \mathcal{P}
 create an instance of the distribution
 fill in the column by sampling from this instance
 record the instance in the metadata
 end
end

2.3 Selection

The selection operator describes the process by which individuals are chosen from the current population to generate the next. Almost always, the likelihood of an individual being selected is determined by their fitness. This is because the purpose of selection is to preserve favourable qualities and encourage some homogeneity within future generations [2].

Fig. 4: The selection process with the inclusion of some lucky individuals.

Algorithm 4: The selection process

Input: population, population fitness, b, l
Output: A set of parent individuals
begin
 calculate n_b and n_l
 sort the population by the fitness of its individuals
 take the first n_b individuals and make them parents
 if *there are any individuals left* **then**
 take the next n_l individuals and make them parents
 end
end

In EDO, a modified truncation selection method is used [8], as can be seen in Figure 4. Truncation selection takes a fixed number, $n_b = \lceil bN \rceil$, of the fittest individuals in a population and makes them the “parents” of the next. It has been observed that, despite its efficiency as a selection operator, truncation selection can lead to premature convergence at local optima [8, 16]. The modification for EDO is an optional stage after the best individuals have been chosen: with some small l , a number, $n_l = \lceil lN \rceil$, of the remaining individuals can be selected at random to be carried forward. Hence, allowing for a small number of randomly selected individuals may encourage diversity and further exploration throughout the run of the algorithm. It should be noted that regardless of this step, an individual could potentially be present throughout the entirety of the algorithm.

After the parents have been selected, there are two adjustments made to the current search space. The first is that the subtypes for each family in \mathcal{P} are updated to only those present in the parents. The second adjustment is a process which acts on the distribution parameter limits for each subtype in \mathcal{P} . This adjustment gives the ability to “shrink” the search space about the region observed in a given population. This method is based on a power law described in [1] that relies on a shrink factor, s . At each iteration, t , every distribution subtype which is present in the parents has its parameter’s limits, (l_t, u_t) , adjusted. This adjustment is such that the new limits, (l_{t+1}, u_{t+1}) are centred about the mean observed value, μ , for that parameter:

$$l_{t+1} = \max \left\{ l_t, \mu - \frac{1}{2}(u_t - l_t)s^t \right\} \quad (1)$$

$$u_{t+1} = \max \left\{ u_t, \mu + \frac{1}{2}(u_t - l_t)s^t \right\} \quad (2)$$

The shrinking process is given explicitly in Algorithm 5. Note that the behaviour of this process can produce reductive results for some use cases and is optional.

Algorithm 5: Shrinking the mutation space

Input: parents, current iteration, \mathcal{P}, M, s
Output: A new mutation space focussed around the parents
begin
 for each distribution subtype in \mathcal{P} **do**
 for each parameter of the distribution **do**
 get the current values for parameter over all parent columns
 find the mean of the current values
 find the new lower (1) and upper (2) bounds around the mean
 set the parameter limits
 end
 end
end

2.4 Crossover

Crossover is the operation of combining two individuals in order to create at least one offspring. In genetic algorithms, the term “crossover” can be taken literally: two bit strings are crossed at a point to create two new bit strings. Another popular method is uniform crossover, which has been favoured for its efficiency and efficacy in combining individuals [18]. For EDO, this method is adapted to support dataset manipulation: a new individual is created by uniformly sampling each of its components (dimensions and then columns) from a set of two “parent” individuals, as shown in Figure 5.

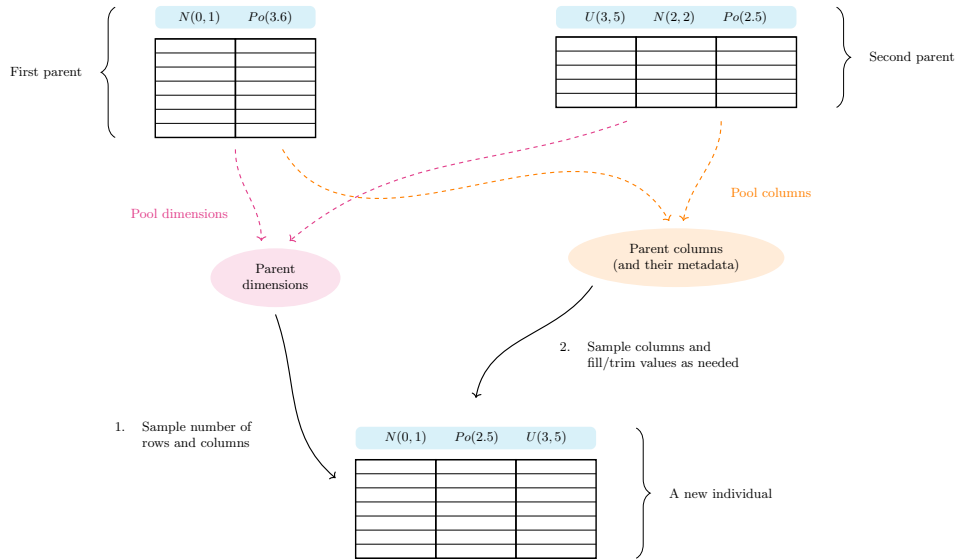

Fig. 5: The crossover process between two individuals with different dimensions.

Algorithm 6: The crossover process

Input: Two parents**Output:** An offspring made from the parents ready for mutation**begin**

collate the columns and metadata from each parent in a pool

sample each dimension from between the parents uniformly

form an empty dataset with these dimensions

for *each column in the dataset* **do**

sample a column (and its corresponding metadata) from the pool

if *this column is longer than required* **then**

| randomly select entries and delete them as needed

end **if** *this column is shorter than required* **then**

| sample new values from the metadata and append them to the column as needed

end

add this column to the dataset and record its metadata

end**end**

2.5 Mutation

Mutation is used in evolutionary algorithms to encourage a broader exploration of the search space at each generation. Under this framework, the mutation process manipulates the phenotype of an individual where numerous things need to be modified including an individual's dimensions, column metadata and the entries themselves. This process is described in Figure 6.

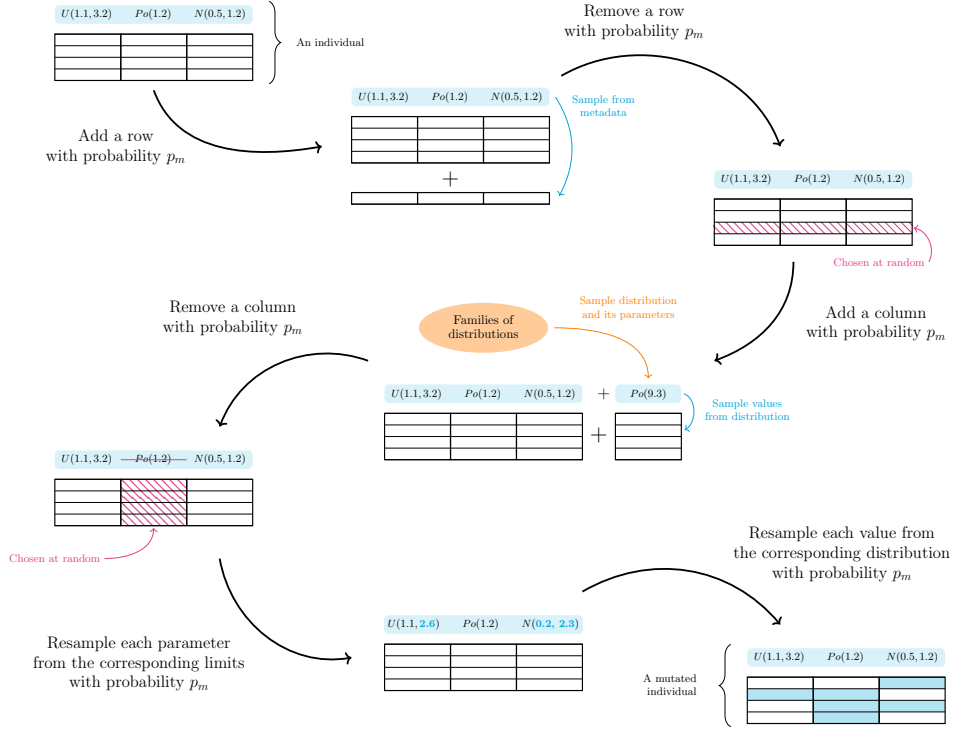

Fig. 6: The mutation process.

As shown in Figure 6, each of the potential mutations occur with the same probability, p_m . However, the way in which columns are maintained assure that (assuming appropriate choices for f and \mathcal{P}) many mutations in the metadata and the dataset itself will only result in some incremental change in the individual's fitness relative to, say, a completely new individual.

3 Examples

3.1 k -means clustering

The following examples act as a form of validation for EDO, and also highlight some of the nuances in its use. The examples will be focused around the clustering of data and, in particular, the k -means (Lloyd's) algorithm. Clustering was chosen as it is a well-understood problem that is easily accessible - especially when restricted to two dimensions. The k -means algorithm is an iterative, centroid-based method that aims to minimise the “inertia” of the current partition, $Z = \{Z_1, \dots, Z_k\}$, of some dataset X :

$$I(Z, X) := \frac{1}{|X|} \sum_{j=1}^k \sum_{x \in Z_j} d(x, z_j)^2 \quad (3)$$

A full statement of the algorithm is given in A.1. However, it should be clear that I may take any non-negative value.

Algorithm 7: The mutation process

Input: An individual, p_m , R , C , \mathcal{P} , w
Output: A mutated individual

```

begin
  sample a random number  $r \in [0, 1]$ 
  if  $r < p_m$  and adding a row would not violate  $R$  then
    sample a value from each distribution in the metadata
    append these values as a row to the end of the dataset
  end
  sample a new  $r \in [0, 1]$ 
  if  $r < p_m$  and removing a row would not violate  $R$  then
    remove a row at random from the dataset
  end
  sample a new  $r \in [0, 1]$ 
  if  $r < p_m$  and adding a new column would not violate  $C$  then
    create a new column using  $\mathcal{P}$  and  $w$ 
    append this column to the end of the dataset
  end
  sample a new  $r \in [0, 1]$ 
  if  $r < p_m$  and removing a column would not violate  $C$  then
    remove a column (and its associated metadata) at random from the dataset
  end
  for each distribution in the metadata do
    for each parameter of the distribution do
      sample a random number  $r \in [0, 1]$ 
      if  $r < p_m$  then
        sample a new value from within the distribution parameter limits
        update the parameter value with this new value
      end
    end
  end
  for each entry in the dataset do
    sample a random number  $r \in [0, 1]$ 
    if  $r < p_m$  then
      sample a new value from the associated column distribution
      update the entry with this new value
    end
  end
end
end

```

This inertia function is often taken as the objective of the k -means algorithm, and is used for evaluating the final clustering. This is particularly true when the algorithm is not being considered an unsupervised classifier where accuracy may be used [7]. With that, the first example is to use this inertia as the fitness function in EDO. That is, to find datasets which minimise I .

In this example, EDO is restricted to only two-dimensional datasets, i.e. $C = ((2, 2))$. In addition to this, all columns are formed from the uniform distribution restricted to the unit interval, $\mathcal{U} := \{U(a, b) \mid a, b \in [0, 1]\}$. The remaining parameters are as follows: $N = 100$, $R = (3, 100)$, $M = 1000$, $b = 0.2$, $l = 0$, $p_m = 0.01$, and shrinkage excluded. Figure 7a shows an example of the fitness (above) and dimension (below) progression of the evolutionary algorithm under these conditions up until the 50th epoch.

There is a steep learning curve here; within the first 50 generations an individual is found with a fitness of roughly 10^{-10} which could not be improved on for a further 900 epochs. The same quick convergence is seen in the number of rows. This behaviour is quickly recognised as preferable and was dominant across all the trials conducted in this work. This preference for datasets with fewer rows makes sense given that I is a summation of non-negative terms (since d is a distance metric.) With that, when k is fixed *a priori*, reducing the number of terms in the second summation quickly reduces the value of I .

Fig. 7a: Progressions for final inertia and dimension across the first 50 epochs with $R = (3, 100)$.

Something that may be seen as unwanted is a compaction of the clusters. Referring to Figure 8a, the best individual shows two clusters but they are all essentially the same point. This kind of behaviour is exhibited in part because it is allowed. There are two immediate ways in which this is allowed: first, that the “trivial” case is included in R and, secondly, that the fitness function does nothing to penalise the reduction in the inter-cluster means, as well as the intra-cluster means. This kind of unwanted behaviour highlights a subtlety in how EDO should be used; experimentation and rigour are required to properly understand an algorithm’s quality.

Consider Figure 8b where EDO was used with $R = (50, 100)$. In this case, the clusters are still dense about a single point despite the trivial case being removed from consideration. Perhaps then, this compact

Fig. 7b: Progressions for final inertia and dimension across the first 50 epochs with $R = (50, 100)$.

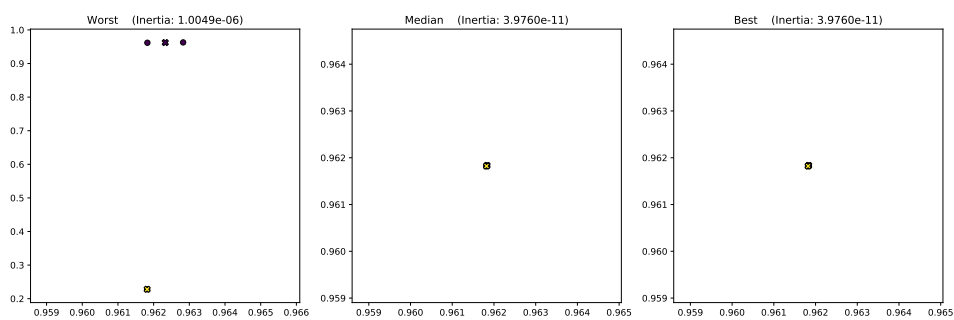

Fig. 8a: Representative individuals from the final generation based on inertia with $R = (3, 100)$. Centroids displayed as crosses.

Fig. 8b: Representative individuals from the final generation based on inertia with $R = (50, 100)$. Centroids displayed as crosses.

clustering is “optimal”. However, more extensive studying may be done. That is, the defined fitness function may require further attention.

Indeed, the final inertia could be considered a flawed or fragile fitness function if it is supposed to evaluate the appropriateness or efficacy of the k -means algorithm. Incorporating the inter-cluster spread to the fitness of an individual dataset can reduce this observed compaction. The silhouette coefficient is a metric used to evaluate the appropriateness of a clustering to a dataset, and is given by the mean of the silhouette value, $S(x)$, of each point $x \in Z_j$ in each cluster:

$$A(x) := \frac{1}{|Z_j| - 1} \sum_{y \in Z_j \setminus \{x\}} d(x, y), \quad B(x) := \min_{k \neq j} \frac{1}{|Z_k|} \sum_{w \in Z_k} d(x, w)$$

$$S(x) := \begin{cases} \frac{B(x) - A(x)}{\max\{A(x), B(x)\}} & \text{if } |Z_j| > 1 \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

The optimisation of the silhouette coefficient is analogous to finding a dataset which increases both the intra-cluster cohesion (the inverse of A) and inter-cluster separation (B). Hence, the inertia is addressed by maximising cohesion. Meanwhile, the spread of the clusters themselves is considered by maximising separation.

Repeating the trials with the same parameters as previously, the silhouette fitness function yields the results summarised in Figure 9. In this case, the datasets produced have reduced overlap with one another whilst maintaining low values in the final inertia of the clustering as shown in Figure 10. Again, the form of the individual clusters is much the same. The low values of inertia correspond to tight clusters, and the tightest clusters are those with a minimal number of points, i.e. a single point. As with the previous example, albeit at a much slower rate, the preferable individuals are those leading toward this case. That

this gradual reduction in the dimension of the individuals occurs after the improvement of the fitness function bolsters the claim that the base case is also optimal.

However, due to the nature of the implementation, any individual from any generation may be retrieved and studied should the final results be too concentrated on the base case. This transparency in the history and progression of the proposed method is something that sets it apart from other methods of the same ilk such as GANs which have a reputation of providing so-called “black box” solutions.

Fig. 9: Progressions for the silhouette and dimension (number of rows) for a run of EDO shown at 100 epoch intervals.

3.2 Comparison with DBSCAN

The capabilities of EDO as a tool for understanding an algorithm are highlighted particularly when comparing an algorithm against another (or set of others) simultaneously. This is done by utilising the freedom of choice in a fitness function for EDO. Consider two algorithms, A and B , and some common metric between them, g . Then understanding their similarities and contrasts can be done by considering the differences in this metric on the two algorithms. In terms of EDO, this means using $f = g_A - g_B$, $f = g_B - g_A$ or $f = |g_B - g_A|$ as the fitness function. By doing so, pitfalls, edge cases or fundamental conditions for the

Fig. 10: Representative individuals from the final generation based on silhouette. Centroids displayed as crosses.

method can be highlighted. Overall, this process allows the researcher to more deeply learn about the method of interest.

As an example of this process, consider the another clustering algorithm of a different form such as Density Based Spatial Clustering of Applications with Noise (DBSCAN) and suppose the objective is to find datasets for which k -means outperforms this alternative. Here there is no concept of inertia as DBSCAN is density-based and is able to identify outliers [5]. As such, a valid (and arguably more appropriate) metric is the silhouette score as defined in (4).

However, an adjustment to the fitness function must be made so as to accommodate for the condition of the silhouette coefficient that there be more than one cluster present. Let $S_k(X)$ and $S_D(X)$ denote the silhouette coefficients of the clustering found by k -means and DBSCAN respectively. Then the fitness function is defined to be:

$$f(X) = \begin{cases} S_D(X) - S_k(X), & \text{if DBSCAN identifies two or more clusters (including noise)} \\ \infty & \text{otherwise.} \end{cases}$$

Note the order of the subtraction here as EDO minimises fitness functions by default.

4 Conclusion

In this paper we have introduced a novel approach to understanding the quality of an algorithm by exploring the space in which their well-performing datasets exist. Following a detailed explanation of its internal mechanisms, a case study in k -means clustering was offered as validation for the method. The method utilises biological operators to traverse the space of all possible datasets in an organic, unrestricted way. The generative nature of the proposed method also provides transparency and richness to the solution when compared to other contemporary techniques for artificial data generation as entire history of individuals is preserved.

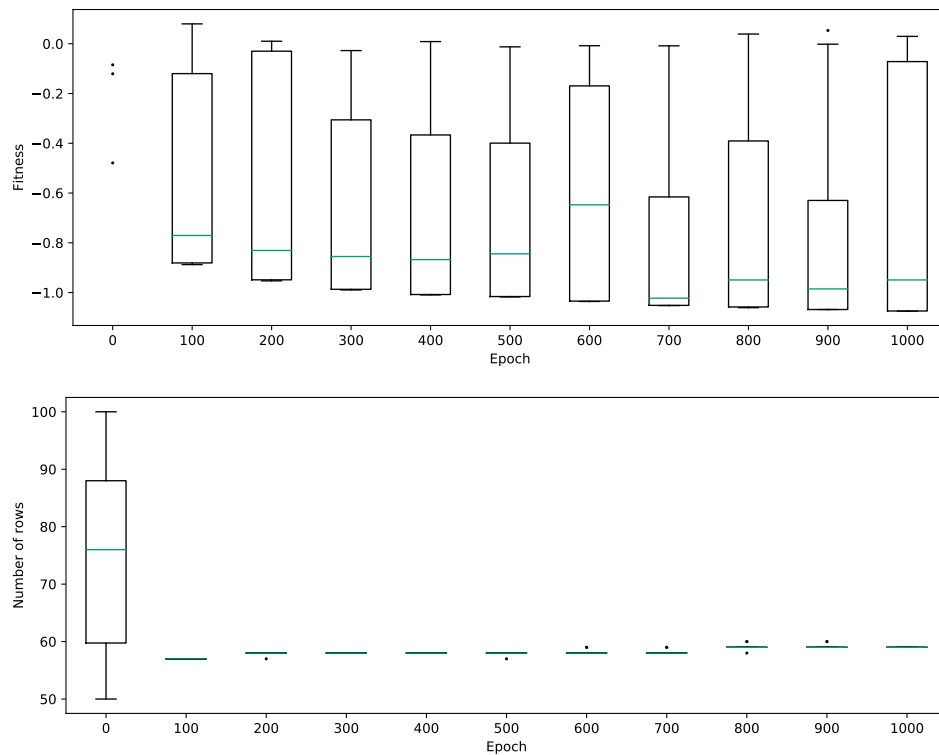

Fig. 11: Progressions for difference in silhouette and dimension for a run of EDO shown at 100 epoch intervals.

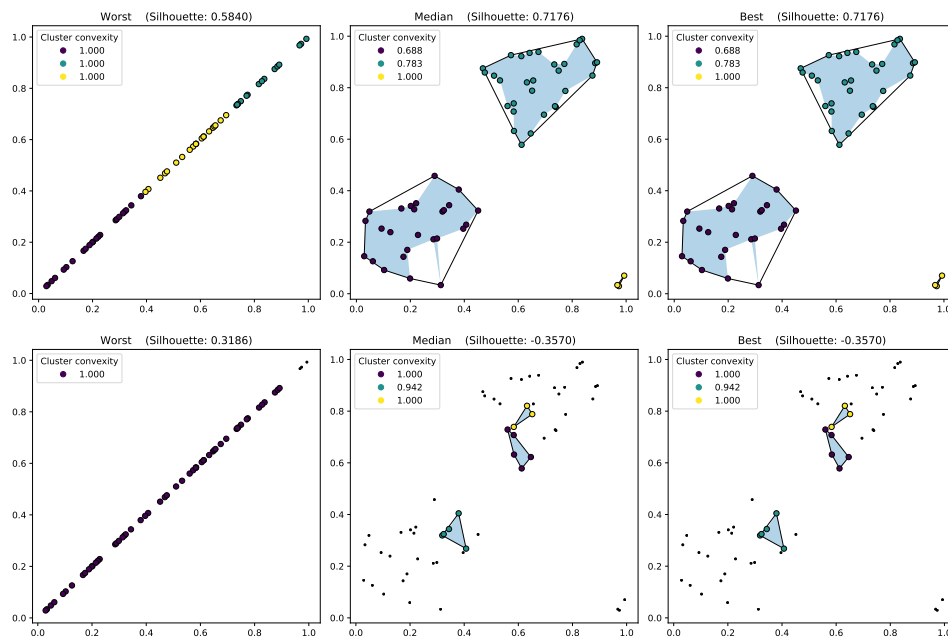

Fig. 12: Representative individuals from the final generation with clusters shown. Convex hull shown as outline, and approximate concave hull shaded. Above by k -means, below by DBSCAN.

The evolutionary dataset optimisation method is dependent on a number of parameters set out in this paper and perhaps the most important of which is the choice of distribution families, \mathcal{P} ; these families set out the general statistical shape of the columns of the datasets that are produced and also control the present data types. The relationship between columns and their associated distribution is not causal and appropriate methods should be employed to understand the structure and characteristics of the data produced before formal conclusions are made as set out in the example provided.

A Appendix

A.1 Lloyd's algorithm

Algorithm 8: *k*-means (Lloyd's)

Input: a dataset X , a number of centroids k , a distance metric d

Output: a partition of X into k parts, Z

begin

 select k initial centroids, $z_1, \dots, z_k \in X$

while *any point changes cluster or some stopping criterion is not met* **do**

 assign each point, $x \in X$, to cluster Z_{j^*} where:

$$j^* = \arg \min_{j=1, \dots, k} \left\{ d(x, z_j)^2 \right\}$$

 recalculate all centroids by taking the intra-cluster mean:

$$z_j = \frac{1}{|Z_j|} \sum_{x \in Z_j} x$$

end

end

A.2 Implementation example

Below is an example of how the Python implementation was used to complete the first example, including the definition of the fitness function.

```
import edo
from edo.pdfs import Uniform
from sklearn.cluster import KMeans

def fitness(dataframe, seed):
    """ Return the final inertia of 2-means on dataframe. """

    km = KMeans(n_clusters=2, random_state=seed).fit(dataframe)
    return km.inertia_
```

```
Uniform.param_limits["bounds"] = [0, 1]
row_limits, col_limits = [3, 100], [2, 2]
```

```
edo.run_algorithm(
    fitness,
    size,
    row_limits,
    col_limits,
    families=[Uniform],
    max_iter=1000,
    best_prop=selection,
    mutation_prob=mutation,
    seed=seed,
    root="out",
    fitness_kwargs={"seed": seed},
)
```
